9

10   **Abstract**

11   Groundwater is used for approximately half of all irrigation agriculture to support global food production.  
12   The impacts of climate change on water resources for sustainable agriculture have led to a rise in  
13   groundwater demand for agriculture, particularly in arid and semi-arid regions such as Ghana. However, in  
14   the Savannah Region of Ghana, groundwater has not been adequately used in small-large scale agricultural  
15   production. The study employed GIS-based Multi-Criteria Decision Making (MCDM) techniques to estimate  
16   groundwater potential zones for irrigation agriculture during the dry season in the Savannah Region of  
17   Ghana. To determine the groundwater potential zones in the region for irrigation development, the study  
18   integrated seven data variables including geology, slope, precipitation, land use and land cover (LULC),  
19   lineament density, drainage density, and soil. Based on each thematic layer's characteristics and  
20   contribution to groundwater recharge, normalised weights were assigned to them. These were later  
21   combined using the weighted overlay analysis technique in ArcGIS to create the map of the groundwater  
22   potential zones. The groundwater potential map was classified into five zones according to their  
23   groundwater potentiality. The classes were very poor 0.12% (43.09km<sup>2</sup>), poor 19.78% (7,051.55km<sup>2</sup>),  
24   moderate 55.62% (19,830.33km<sup>2</sup>), good 22.64% (8,071.57km<sup>2</sup>), and excellent 1.84% (654.68km<sup>2</sup>)  
25   respectively. The map which shows the spatial distribution of the groundwater potential zones of the area  
26   will assist stakeholders in groundwater development for irrigation agriculture to supply farming communities  
27   with water for sustainable crop cultivation in the Savannah Region, while at the same time serving as  
28   reference material for future research studies.

43 **1.1 Introduction**

44 Groundwater is considered one of the most vital resources, and the greatest available freshwater found  
 45 below the surface of the earth in the pore cracks and fissures of rock and sediments (Díaz-Alcaide &  
 46 Martínez-Santos, 2019; Naghibi et al., 2015). In contrast to about 0.3% of surface water in the form of lakes,  
 47 marshes, reservoirs, and rivers, around 30% of the planet's freshwater is hidden and reserved as  
 48 groundwater (Senanayake et al., 2016). The principal source of groundwater, which percolates in the  
 49 aquifer through the soil pores, especially in the dry savannah, is rainwater. According to the IPCC (2021),  
 50 groundwater recharge has increased due to rising precipitation intensities. This resource is increasingly  
 51 relied on for several uses including irrigation agriculture due to the rapid growth of the world population and  
 52 changing climates (Arulbalaji et al., 2019; IPCC, 2021). Approximately half of all irrigated agricultural  
 53 production in the world is sourced from groundwater (GWP, 2013). Globally, agricultural and industrial crops  
 54 as well as livestock are grown using around 70% of the world's groundwater withdrawals, while 30% of all  
 55 irrigation water utilized worldwide is derived from underground sources (FAO, 2022). This contributes to  
 56 economic growth, ecological balance and improved livelihoods in groundwater irrigation environments. In  
 57 many places of the world, including Ghana, ensuring food security requires the sustainable development  
 58 of groundwater due to a changing climate. Though a preferred choice of drinking water in remote areas of  
 59 Ghana (Osiakwan et al., 2022), groundwater is also used for small-scale cultivation (Adam & Appiah-Adjei,  
 60 2019). With increasing intensities and fluctuations of climatic variables such as rainfall and droughts,  
 61 coupled with rising demand for food and water, there is a need to double the rate of food production and  
 62 water supply. The single cropping season in the Savannah ecological zones of Ghana do not seem to  
 63 present the opportunity to meet the increasing food demand. Meanwhile, agriculture is the mainstay of  
 64 inhabitants of the area (GSS, 2021). Thus, an alternative source of water (groundwater) needs to be  
 65 explored for such a development. This could help improve farmers productivity and livelihoods throughout  
 66 the year. To make groundwater irrigation development decisions by stakeholders such as the Regional  
 67 Authorities, the Government of Ghana, and the external investors, there is the need to understand the  
 68 groundwater potential of the region. However, there is a paucity of knowledge regarding the potential areas  
 69 of groundwater in the Savannah Region. Hence, the study seeks to bridge this knowledge gap by using  
 70 geospatial techniques (geographic information system and remote sensing) to estimate the groundwater  
 71 potential of the Savannah Region such that stakeholders including the Ministry of Agriculture can be guided  
 72 by the findings of the study.

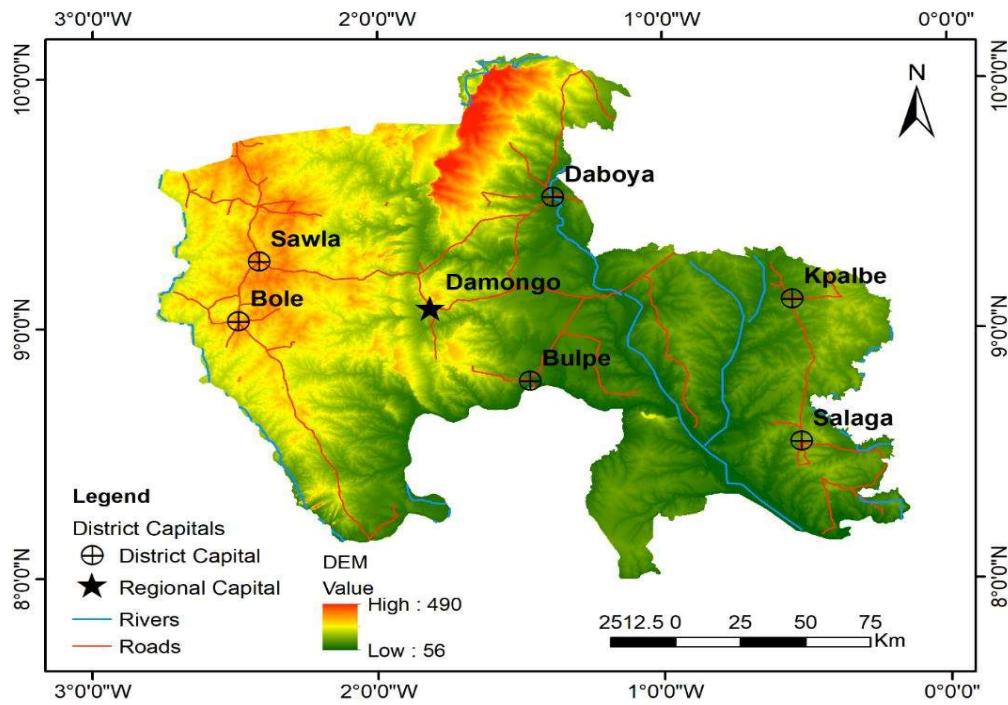

73 Geospatial technologies (GIS and remote sensing) have been used widely in natural resources assessment  
 74 including mapping of groundwater potential zones in diverse locations across the globe (Arulbalaji et al.,  
 75 2019; Asante et al., 2022, 2022; Aslan & Çelik, 2021; Das et al., 2019; Díaz-Alcaide & Martínez-Santos,  
 76 2019; Owolabi et al., 2020). Due to the pricy and time-consuming nature of traditional methods which are  
 77 often done through ground surveys for identifying, delineating and mapping groundwater potential zones  
 78 (Israil et al., 2006), GIS and remote sensing techniques have emerged as cost-effective tools for  
 79 groundwater potential mapping in recent times (Adiat et al., 2012; Arulbalaji et al., 2019). The literature  
 80 reveals that GIS and remote sensing techniques for groundwater exploration are very cost-effective and;  
 81 thus recommended for such activities, particularly before detailed and expensive land-based surveys are  
 82 conducted (Arulbalaji et al., 2019). The groundwater potential zones of this study were defined using a  
 83 blend of Analytical Hierarchy Process (AHP) which is a multi-criteria decision-making technique and  
 84 geospatial approaches. In 1980, Thomas Saaty invented the AHP model, a useful tool for addressing  
 85 complicated decision-making, which has been adopted in groundwater-related disciplines (Arulbalaji et al.,  
 86 2019; Kpiebaya et al., 2022; Owolabi et al., 2020). The method is helpful for decomposing complex  
 87 decisions into a series of pair-wise comparisons and then integrating the findings. The AHP tool is also an  
 88 appropriate method for assessing the consistency of the outcome, which reduces subjectivity in the  
 89 decision-making process. Therefore, the objective of the study is to estimate the groundwater potential of  
 90 the Savannah Region using the AHP method to guide policy makings with regard to groundwater resource  
 91 planning and management.

93  
94  
95

96 **2. Methodological Approach**

97 **2.1 Study Area**

98 The Savannah Region is one of the sixteen regions of Ghana located within the guinea savannah  
99 agroecological zone. It is the largest in landmass among all the regions in Ghana with an area of about  
100 46,922 km<sup>2</sup>, or nearly 1/5 of Ghana's total geographical area. The Upper West Region anchors the region  
101 on the north, the Bono and Bono East Regions on the south, the North-East and Northern Regions on the  
102 west, and the Republic of Cote d'Ivoire on the west. Approximately 2.69 million hectares of land in the  
103 region are used for agriculture (farming and animal rearing). Additionally, it possesses roughly 1.67 million  
104 hectares of land ostensibly suitable for growing a variety of crops, including maize, rice, millet, sorghum,  
105 yam, cassava, soybeans, and groundnuts. The area has two major inland rivers (the White and the Black  
106 Volta; tributaries of the Volta Lake in Ghana) that serve as the major drainage channels of the region. The  
107 region, according to GSS (2021), has about 653,266 inhabitants of whom about 70.4 per cent live in rural  
108 areas whilst the remaining 29.6 per cent live in urban centres. The majority of these people are smallholder  
109 farmers who rely heavily on rainfed agriculture for survival. Meanwhile, the region has a unimodal rainfall  
110 regime and receives an annual rainfall of between 1000-1500mm. This presents economic challenges to  
111 the people of the area, especially during the dry season. The increasing demand for water - for domestic  
112 and agricultural purposes - is becoming an issue of concern for development authorities in the area leading  
113 to the construction of smaller surface dams for some communities. However, most of these dams are not  
114 able to withstand the intensity of the dry season's weather; thus, becoming ephemeral. **Figure 1** is the map  
115 of the Savannah Region showing the major rivers and elevation of the area.

116  
117 **Figure 1:Map of the Savannah Region showing the major rivers and elevation**

118 Author's construct (2022)

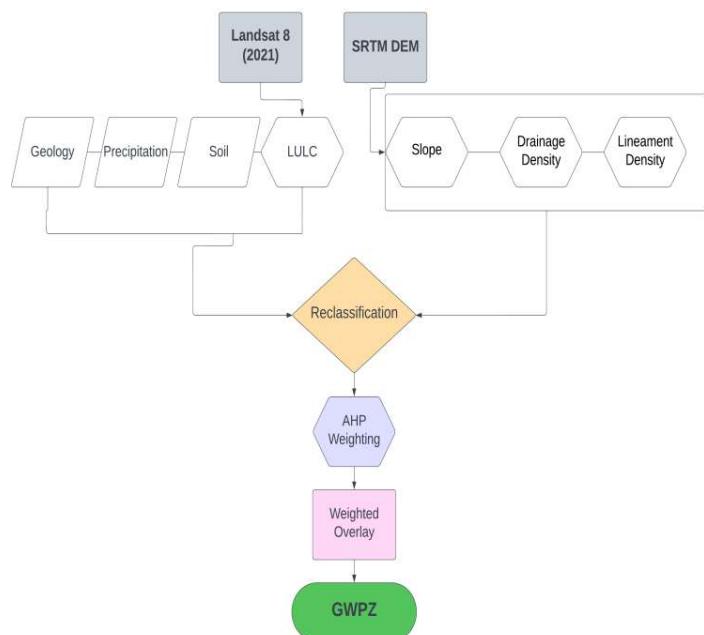

119

120 **2.2 Materials and Methods**

121 In this study, geospatial techniques were used to define the groundwater potential zones of the Savannah  
122 Region. A total of 7 thematic layers of information about the region, including geology, slope, precipitation,  
123 land use/land cover (LULC), lineament density, drainage density, and soil were selected using knowledge-  
124 based experience and understanding. Though there are varieties of factors including geology,  
125 geomorphology, land use/land cover (LULC), drainage density, lineaments, rainfall, soil, roughness, slope,  
126 curvature, topographic position index, and topographic wetness index used for groundwater potential  
127 mapping and modelling (Arulbalaji et al., 2019), this study selected only seven of the factors. These factors  
128 were selected based on previous studies that have applied those variables for groundwater potential  
129 mapping (Abebreste et al., 2022; Kpiebaya et al., 2022; Nasir et al., 2018; Osiakwan et al., 2022; Tolche,  
130 2021)

131 The data used for this study were obtained from secondary sources and, the software used for the remotely  
132 sensed image pre-processing and geospatial analysis were ENVI 5.3 and ArcGIS 10.8. For the creation of  
133 LULC of the region, the ENVI software was used for colour compositing and classification. The study area  
134 map was derived from the Shuttle Radar Topographic Mission (SRTM-30m resolution) data using the  
135 regional boundary shapefile. The SRTM data was obtained from the United States Geological Survey  
136 (USGS) EarthExplorer.

137 From SRTM data, the slope, lineament, and drainage densities were produced. Line density in the spatial  
138 analyst tool of ArcGIS software was used to prepare the density from the drainage and lineament. The soil  
139 data were acquired from the Food and Agriculture Organization of the United Nations (FAO-UN) data  
140 catalogue whilst the geology data was downloaded from the USGS World Geologic Maps portal. The  
141 precipitation data was also obtained from the Climate Research Unit of the University of East Anglia portal  
142 for 2021 in NetCDF format. This was imported into ArcGIS using the NetCDF tool under the multi-dimension  
143 tools of the software. The average annual precipitation was converted into point vector data and later, the  
144 spatial distribution of the precipitation was produced using the kriging interpolation tool. The flowchart of  
145 the methodology used to map the groundwater potential zones is presented in [Figure 2](#).

146

147 **Figure 2: Flowchart of the methodology**

148 Author's construct (2022)

149      **2.3 The AHP-Geospatial Analysis**

150      The Analytic Hierarchy Process is one of the widely used multi-criteria decision-making techniques across  
 151      several disciplines including geospatial analysis (Arulbalaji et al., 2019; Mallick et al., 2019; Owolabi et al.,  
 152      2020). The Technique was developed by Professor Saaty in 1981 to aid in complex decision-making by  
 153      integrating several factors (choices). In this study, a total of seven (7) groundwater influencing factors were  
 154      used for the assessment. The free web-based model of the AHP model developed by Goepel (2018) was  
 155      used to assign weights to each of the seven factors. The parameter that contributes to groundwater  
 156      recharge the most, is given the highest weight. Thus, a high weight shows a parameter with a greater  
 157      impact, and a low weight shows a parameter with little impact on groundwater potential. Each criterion's  
 158      weight was determined using Saaty's scale of relative relevance values (1-9). Additionally, the weights were  
 159      assigned taking into account the study of prior research and field experience. According to Saaty's scale of  
 160      relative importance, a value of 9 indicates extreme importance, 8 indicates between extreme and very  
 161      strong importance, 7 indicates very strong importance, 6 indicates between strong and very strong  
 162      importance, 5 indicates strong importance, 4 indicates between moderate and strong importance, 3  
 163      indicates moderate importance, 2 indicates between equal and moderate importance, and 1 indicates equal  
 164      importance. A pair-wise comparison matrix has been used to compare all of the parameters to determine  
 165      their individual influence on groundwater development ([Table 1](#)).

166      **Table 1: Pairwise Comparison Matrix of the factors Influencing Groundwater Potentially**

|               | Geology | Slope | Precipitation | LULC | Lineament | Drainage | Soil |
|---------------|---------|-------|---------------|------|-----------|----------|------|
| Geology       | 1       | 1     | 2             | 3    | 2         | 1        | 2    |
| Slope         | 1       | 1     | 2             | 2    | 2         | 1        | 3    |
| Precipitation | 1/2     | 1/2   | 1             | 1    | 2         | 1/2      | 2    |
| LULC          | 1/3     | 1/2   | 1             | 1    | 1         | 1/2      | 1    |
| Lineament     | 1/2     | 1/2   | 1/2           | 1    | 1         | 1/2      | 2    |
| Drainage      | 1       | 1     | 2             | 2    | 2         | 1        | 5    |
| Soil          | 1/2     | 1/3   | 1/2           | 1    | 1/2       | 1/5      | 1    |

167  
 168  
 169      The subclasses of the parameters were reclassified in ArcGIS using the natural breaks classification  
 170      technique to assign the suitability class ratings. On a scale from 1 to 5, higher suitability class ranges were  
 171      ranked and assigned values based on their relative impact on groundwater recharge with 5 being the range  
 172      with very high impact and 1 being the range with very low impact ([Table 2](#)).

190 **2.4 Results and Discussion**

191 **2.4.1 Geology**

192 Geology is one of the important factors that determine the availability of groundwater in an area. The  
193 location of aquifers, confining units, and their outcrops are determined by geological factors. The  
194 composition of morphological layers, which affect groundwater flow, recharge, and discharge, is dictated  
195 by geological factors; thus, contributes to determining the quantity and rate of infiltration, as well as surface  
196 runoff and groundwater quality ([Alsharhan & Rizk, 2020](#)). The data for the analysis of the geological  
197 formation of the study area was obtained from the USGS World Geologic Maps portal. The results showed  
198 two major geologic formations including Precambrian and Ordovician in the study ([Figure 3a](#)). The  
199 Precambrian formation occupies more than half of the study area. While the Precambrian geology in Ghana  
200 is mostly characterised by metamorphic rocks such as mafic gneiss, quartzite, schist, phyllite, quartzite,  
201 shale, and sandstone rocks, the Ordovician geology is characterised by sheer, thin-bedded quartzitic  
202 sandstones with siltstones and mudstones, along with coarse-grained, feldspathic sandstones ([Dapaah-](#)  
203 [Siakwan & Gyau-Boakye, 2000](#); [Persits et al., 1997](#)). In comparison with the Precambrian geologic  
204 formation, the Ordovician geology of upper voltaian sandstone is argued to possess significant amounts of  
205 groundwater. This makes the southeastern area of the Savannah Region highly favourable for groundwater  
206 recharge. Though the Precambrian also contain some levels of groundwater, this water forms through  
207 secondary permeability means such as rock fractures, joints and faults ([Dapaah-Siakwan & Gyau-Boakye,](#)  
208 [2000](#)), making the north-western part of the region less favourable for groundwater development.

209 **2.4.2 Slope**

210 The slope, which expresses how steep the ground surface is, is an important topographical feature and  
211 influencing factor of groundwater. Slope provides crucial details on the types of geology and geodynamic  
212 processes at work at the regional level ([Arulbalaji et al., 2019](#); [B. Das et al., 2019](#)). The slope has a  
213 significant impact on the surface runoff and infiltration rate of a region. Steeper slopes allow for little  
214 infiltration during rainfall while gentle slopes allow significant infiltration. Thus, the rapid flow of water along  
215 steep slopes reduces the groundwater recharge of an area. In this case, the water has less time to settle  
216 down and recharge the saturated zone ([De Reu et al., 2013](#)). The slope of the Savannah Region is shown  
217 in [Figure 3b](#). The slope values were reclassified into five classes ranging from very low (<0.93%) to very  
218 steep (>6.56%) sloping areas. Steeper slopes are identified in the northwestern part of the region while  
219 lower slopes are identified in the south-eastern side of the study area. For steeper slopes, lesser weights  
220 were assigned and vice versa. This suggests that the southeastern section of the Savannah Region  
221 experiences more infiltration than runoff, whilst the northern part experiences higher runoff than infiltration.

222 **2.4.3 Precipitation**

223 The primary water source in the hydrological cycle and the most important determining factor for a region's  
224 groundwater is precipitation which includes rainfall. The study used the 2021 rainfall data for the analysis.  
225 Studies revealed that areas that receive more rain during the year have a higher probability of groundwater  
226 whilst areas that receive less rainfall are less likely to have good groundwater zones ([Adam & Appiah-Adjei,](#)  
227 [2019](#); [B. Das et al., 2019](#); [Owolabi et al., 2020](#)). The amount and length of rainfall have an impact on  
228 infiltration. Whereas less intensive and extended duration rain influences high infiltration than runoff, greater  
229 intensity and short duration rain instigates less infiltration and more surface runoff ([Arulbalaji et al., 2019](#)).  
230 In the Savannah Region, rainfall varies from 1,059 to 1,200mm per year ([Figure 3c](#)). Using the ordinary  
231 kriging interpolation approach, a map of the spatial distribution of rainfall was created. The rainfall values  
232 were reclassified ([Table 2](#)) into Very Low (1,059.09-1,099.00 mm), Low (1,099.00-1,129.83 mm), Moderate  
233 (1,129.83-1,166.11 mm), High (1,166.11-1,216.00 mm), and Very High (1,216.00-1,290.37 mm). From the  
234 result ([Figure 3c](#)), the south-eastern area of the Savannah Region appears to receive more precipitation  
235 than the north-western zone of the Region. This makes the southeastern zones more favourable for  
236 groundwater development for domestic and agricultural uses.

237 **2.4.4 LULC**

238 LULC provides guidance on groundwater requirements as well as critical data on infiltration, soil moisture,  
239 groundwater, surface water, etc. ([Arulbalaji et al., 2019](#)). There are different types of land uses in the  
240 Savannah Region. However, the study examined only four including built-up/bare lands, farmlands,  
241 vegetation and water ([Figure 3d](#)). For the land use/cover classification, the Landsat 8 OLI data for 2021  
242 was acquired from USGS with less than 10% cloud cover. The data was downloaded between February  
243 and April 2021. This was to ensure that the data acquired will meet the 10% cloud cover requirement.

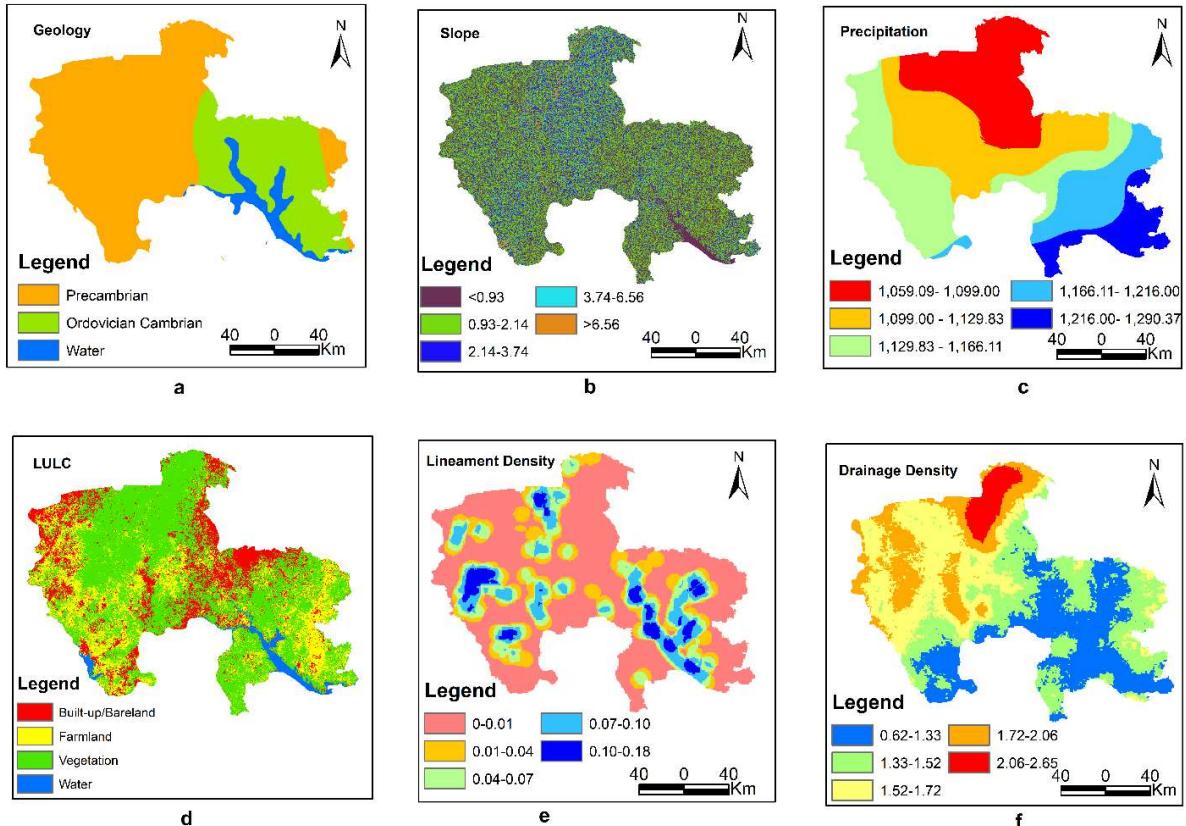

244 Among all the classes, vegetation predominates over the others. This was followed by built-up/bare lands,  
245 farmlands, and water. The north-western area of the Savannah Region has more vegetation which is  
246 attributable to the presence of the Mole National Park. The restrictions imposed by the Park's management  
247 authority and the Ghana Wildlife Division of the Forestry Commission limit anthropogenic activities in the  
248 area. Thus, preserving its vegetation cover. Built-up/bare lands appear to be the second largest land  
249 use/cover in the area due to the availability of bare lands, particularly during the dry season due to the  
250 prevalence of bush burning in the area. In comparison to built-up/bare lands, LULC types like vegetation  
251 and farmlands store a significant proportion of water for infiltration ([Arulbalaji et al., 2019](#); [Rajaveni et al.,](#)  
252 [2017](#); [Ghosh et al., 2015](#)). The vegetation, farmland, and water are given higher weights whilst built-up/bare  
253 land is a lower weight ([Table 2](#)).

#### 254 **2.4.5 Lineament density**

255 Lineaments are weak surfaces with linear or curvilinear features such as fractures, joints, and faults. that  
256 structurally control groundwater infiltration ([Mallick et al., 2019](#)). Their comparatively linear alignments on  
257 the satellite picture make it easy to discriminate ([Arulbalaji et al., 2019](#)). The faulting and fracture zones  
258 dictate higher porosity and permeability which are generally associated with lineaments ([Yeh et al., 2016](#)).  
259 The lineaments were extracted using the ArcGIS curvature tool which was later used for line detection and  
260 digitizing for the lineament density. [Figure 3e](#) shows the lineament density map that was created using  
261 ArcGIS software's line density feature. After carefully analysing the results, the data were divided into five  
262 classes including Very Low (0.02-0.47 km/km<sup>2</sup>), Low (0.47-0.73 km/km<sup>2</sup>), Moderate (0.73-0.96 km/km<sup>2</sup>),  
263 High (0.96-1.21 km/km<sup>2</sup>), and Very High (1.21-1.72 km/km<sup>2</sup>). Studies suggest that areas with higher  
264 lineament density are associated with higher groundwater potential whilst areas with lower lineament  
265 density are associated with lower groundwater potential ([Yeh et al., 2016](#); [Arulbalaji et al., 2019](#); [Mallick et](#)  
266 [al., 2019](#); [Owolabi et al., 2020](#)). Therefore, higher weights were assigned to higher lineament density values  
267 and vice versa in this study.

#### 268 **2.4.6 Drainage density**

269 Drainage density, which represents the ratio of total lengths of channel networks per unit area, is indicated  
270 to have a significant influence on groundwater availability ([Arulbalaji et al., 2019](#); [Owolabi et al., 2020](#)). The  
271 drainage system is lithology-dependent and serves as a significant determinant of infiltration rate.  
272 Permeability has an opposite relationship with drainage density. As a result, it plays a crucial role in defining  
273 the groundwater potential zone. A drainage basin's drainage density is calculated by dividing the sum of  
274 the lengths of its rivers by the area of the drainage basin ([Yeh et al., 2016](#)). Low infiltration due to high  
275 drainage density makes the north-western part of the Savannah Region less favourable for groundwater  
276 development. Low drainage density in the southeastern side of the region translates to high infiltration,  
277 which raises the groundwater potential of the area. The drainage density ([Figure 3f](#)) of the study was  
278 reclassified into very poor (0.62-1.33 km/km<sup>2</sup>), poor (1.33-1.52 km/km<sup>2</sup>), moderate (1.52-1.72 km/km<sup>2</sup>),  
279 good (1.72-2.06 km/km<sup>2</sup>), and excellent (2.06-2.65 km/km<sup>2</sup>). In this study, lower drainage density values  
280 were assigned higher rates whilst higher drainage density values were assigned lower values.

281

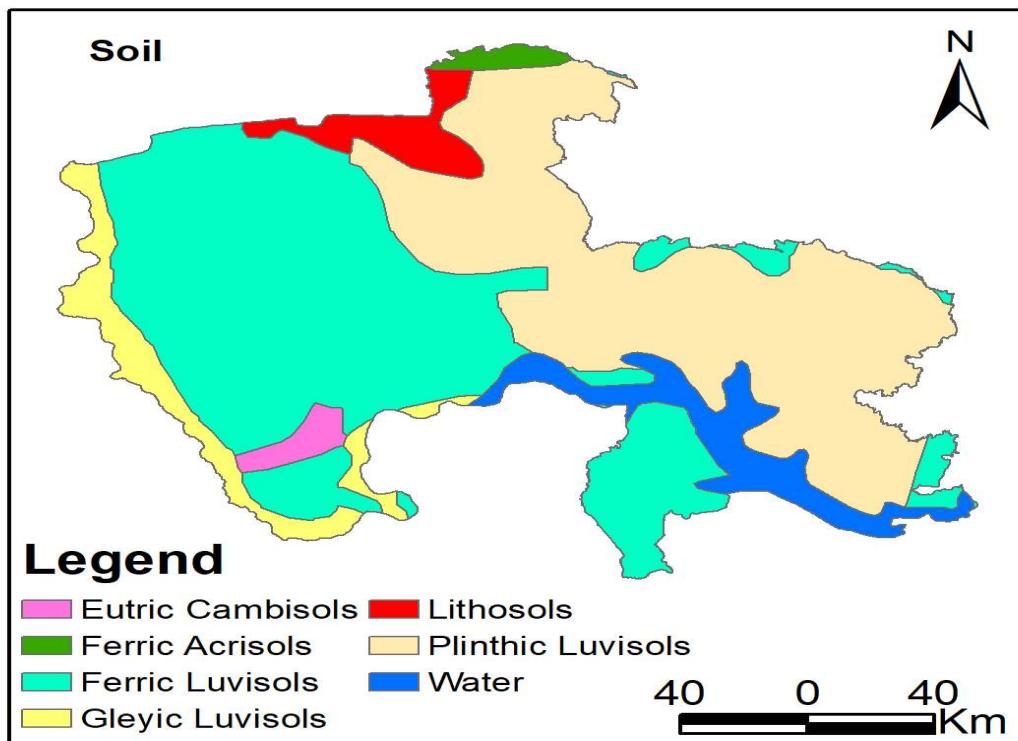

282 **Figure 3a-g: Maps of the Various Parameters**

283

284 **2.4.7 Soil**

285 Soil is another parameter that determines the rate of infiltration of water underground. A review of the  
 286 literature suggests that soil types significantly affect the volume of water seeping into soil layers which  
 287 consequently affects the groundwater recharge of an area ([Arulbalaji et al., 2019](#); [Das et al., 2019](#); [Das, 2017](#); [Yeh et al., 2016](#)). In the study area, a total of six soil types were identified. These include [eutric cambisols](#), [ferric acrisols](#), [ferric luvisols](#), [gleytic luvisols](#), [lithosols](#) and [plinthic luvisols](#). After considering the type of soil and its capacity to retain water, weights are intuitively assigned to each soil component. Soils such as [lithosols](#) or [rigosols](#) are associated with high water-holding capacity and; thus, have a high probability of groundwater development. However, [acrisols](#) have lesser water-holding capacity; hence, has little impact on groundwater recharge. This accounts for the reasons for rating [lithosols](#) very high and [acrisols](#) low ([Figure 4](#)). As presented in [Figure 4](#), [ferric](#) and [plinthic luvisols](#) are the predominant soil types in the Savannah Region

296

297

298 **Figure 4: Soil Map of the study area**

299

300 **2.4.8 Criteria Influence on groundwater development**

301 The study determined the amount of influence each parameter has on groundwater recharge using the  
 302 AHP technique. The results in [Table 3](#) indicate that drainage density has the highest (22.0%) influence on  
 303 groundwater development in the Savannah Region. This is followed by geology (20.5%), Slope (20.1%),  
 304 and Precipitation (11.9%). The rates of influence were used in this study to undertake the weighted overlay  
 305 analysis in ArcGIS to estimate the final groundwater potential zone map. The consistency ratio computed  
 306 from the weights or rates of influence was 0.01983, equivalent to 2.0%. This implies that the weights  
 307 assigned to the parameters were consistent since the ratio estimated was less than 10%.

308 **Table 3: Parameter weights and rate of influence on groundwater recharge**

| Criterion                | Weights        | Influence     |
|--------------------------|----------------|---------------|
| Geology                  | 0.205          | 20.5%         |
| Slope                    | 0.201          | 20.1%         |
| Precipitation            | 0.119          | 11.9%         |
| LULC                     | 0.091          | 9.1%          |
| Lineament density        | 0.097          | 9.7%          |
| Drainage density         | 0.220          | 22.0%         |
| Soil                     | 0.067          | 6.7%          |
| <b>Sum</b>               | <b>1.00</b>    | <b>100.0%</b> |
| <b>Consistency Ratio</b> | <b>0.01983</b> | <b>2.0%</b>   |

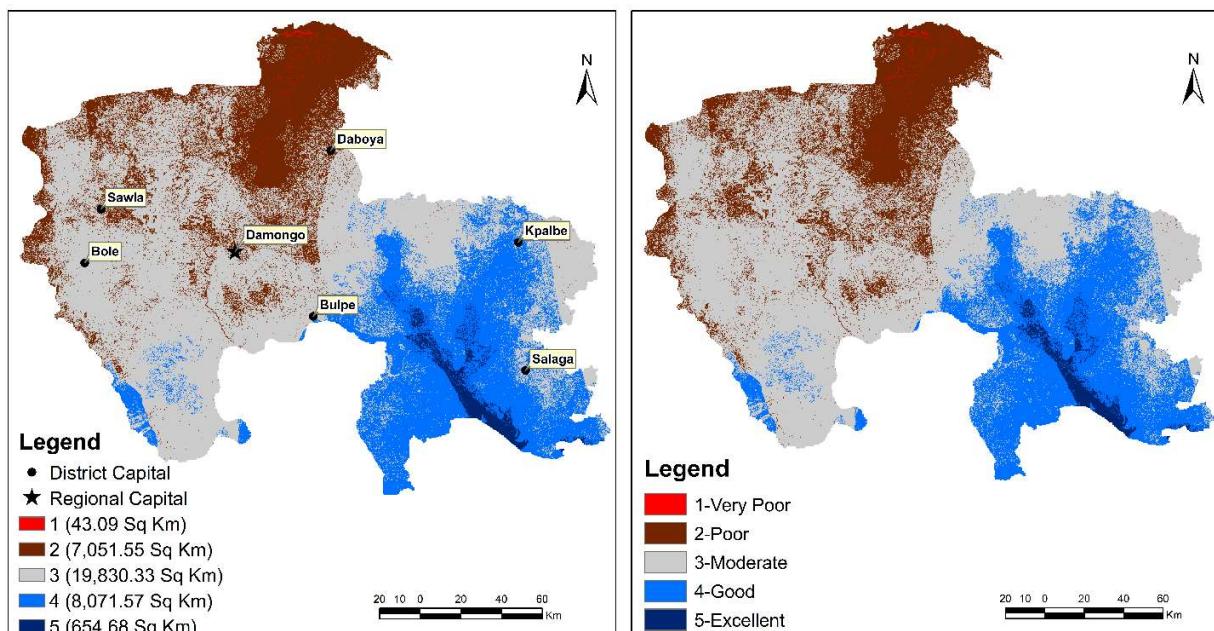

309

310

311 **2.4.8 Groundwater Potential Zones of the Savannah Region**

312 Groundwater is an important source of water supply to both rural and urban environments in arid and semi-  
 313 arid regions. Groundwater is a replenishable resource that supports domestic, agricultural and industrial  
 314 uses. This resource has been impacted by climate change due to anthropogenic footprints on planet earth.  
 315 Arulbalaji et al. (2019) noted that, recently, the recharge of this priceless life-sustaining resource has been  
 316 greatly diminished as a result of different anthropogenic activities and imbalanced development.  
 317 Meanwhile, the resource has helped other countries boost their agricultural productivity, contributing  
 318 significantly to food security efforts. Henceforth, the planning and sustainable development of a region  
 319 depend heavily on having a better grasp of the groundwater potential of the area. Such details are  
 320 necessary for the planning and construction of the required infrastructure that will enhance the processes  
 321 of groundwater development and optimum utilisation. According to the hydrological parameters of the  
 322 Savannah Region (Figure 5), excellent and good groundwater exist in the southeast. The findings of the  
 323 study reveal that more than half (55.62%), representing a total area of about 19,830.33 km<sup>2</sup>, is moderately  
 324 good for groundwater development. Areas with good and excellent groundwater potential zones were  
 325 estimated at 22.64% and 1.84%, translating to a total area of 8,071.57 km<sup>2</sup> and 654.68 km<sup>2</sup> respectively.  
 326 However, about 0.12% and 19.78%, representing an area of 43.09 km<sup>2</sup> and 7051.55 km<sup>2</sup> of the entire study  
 327 area have (very) poor groundwater potential zones. Cumulatively, the study established that about 24.48%  
 328 of the study area can be used for groundwater development while 19.9% is not conducive to groundwater  
 329 recharge. Generally, zones with excellent and good groundwater potential are associated with areas with  
 330 high rainfall, high drainage density, high lineament density, high vegetation cover, and low slopes  
 331 (lowlands/valleys) which also have strong infiltration potential. The findings of the study are consistent with  
 332 the study by Arulbalaji et al. (2019). Therefore, the south-eastern areas that include Salaga, Kpalbe, and  
 333 Buipe could be explored further by stakeholders to develop irrigation schemes for farmers in those areas.  
 334 This will enhance the sustainable agricultural production of the area and provide livelihood support systems  
 335 for farmers during the dry season.

336

337

338 **Figure 5: Map of groundwater potential zones of the Savannah Region**

339

340

341

342 **2.5 Conclusion**

343 The study has attempted to estimate groundwater potential zones of the Savannah Region of Ghana using  
344 geospatial techniques and the Analytic Hierarchy Process (AHP) method. It is necessary to assess the  
345 groundwater resource in the area to assist prospective groundwater development agencies, farmers, and  
346 the local government in making effective groundwater development planning, management, and investment  
347 decisions. The study offers insights into groundwater availability in the Savannah Region for effective  
348 planning and management for domestic, industrial and agricultural applications. The parameters that were  
349 used in the estimation of the groundwater potential of the region included geology, slope, precipitation,  
350 LULC, lineament density, drainage density, and soil. The groundwater potential zones were created using  
351 the weighted overlay approach in ArcGIS. The resulting map was classified into five zones ranging from  
352 excellent to very poor potential areas. Over 55% of the Savannah Region has moderate groundwater  
353 potential. While 19.9% of the region is poorly suitable for groundwater development, about 24.48% of it has  
354 favourable potential for groundwater development. This implies that the resource, when adequately  
355 harnessed, will propel the region's agricultural production to support the expanding population of Ghana.
